ABSTRACT
Structured synchronous reactive programming (SSRP) augments classical structured programming (SP) with continuous interaction with the environment. We advocate SSRP as viable in multiple domains of reactive applications and propose a new abstraction mechanism for the synchronous language Céu: Organisms extend objects with an execution body that composes multiple lines of execution to react to the environment independently. Compositions bring structured reasoning to concurrency and can better describe state machines typical of reactive applications. Organisms are subject to lexical scope and automatic memory management similar to stack-based allocation for local variables in SP. We show that this model does not require garbage collection or a free primitive in the language, eliminating memory leaks by design.

1. INTRODUCTION
Reactive applications interact continuously and in real time with external stimuli from the environment. They represent a wide range of software areas and platforms: from games in powerful desktops and “apps” in capable smart phones, to the emerging internet of things in constrained embedded systems.

Research on special-purpose reactive languages dates back to the early 80’s, with the co-development of two complementary styles [4, 20]: The imperative style of Esterel [7] organizes programs with structured control flow primitives, such as sequences, repetitions, and parallelism. The dataflow style of Lustre [15] represents programs as graphs of values, in which a change to a node updates its dependencies automatically. Both styles rely on the synchronous execution hypothesis which states that the input and corresponded output in reactions to the environment are simultaneous because, in this context, internal computations should run infinitely faster than the rate of events [20].

In recent years, Functional Reactive Programming (FRP) [26] has modernized the dataflow style, inspiring a number of languages and libraries, such as Rx (from Microsoft), React (from Facebook), and Elm [11]. In contrast, the imperative style of Esterel is confined to the domain of real-time embedded control systems. As a matter of fact, imperative reactivity is now often associated to the observer pattern, typical in object-oriented systems, due to its heavy reliance on side effects [17, 22]. However, short-lived callbacks (i.e., the observers) eliminate any vestige of structured programming, such as support for long-lasting loops and automatic variables [3], which are elementary capabilities of imperative languages. In this sense, callbacks actually disrupt imperative reactivity, becoming “our generation’s goto”.

We believe that all domains of reactive applications can benefit from the imperative style of Esterel, which we now refer to as Structured Synchronous Reactive Programming (SSRP). SSRP extends the classical hierarchical control constructs of Structured Programming (SP) (concatenation, selection, and repetition [13]) to support continuous interaction with the environment. In contrast with FRP, SSRP retains structured and sequential reasoning of concurrent programs, bringing the historical dichotomy between functional and imperative languages to the reactive domain. However, the original rigorous semantics of Esterel, which focuses on static safety guarantees, is not suitable for other reactive application domains, such as GUIs, games, and distributed systems. For instance, the lack of abstractions with dynamic lifetime makes it difficult to deal with virtual resources such as graphical widgets, game units, and network sessions.

In practical terms, SSRP provides three extensions to SP: an

---
“await <events>” statement that suspends a line of execution until the referred event occurs, keeping all context alive; parallel constructs to compose multiple lines of execution and make them concurrent; and an orthogonal mechanism to abort parallel compositions. The `await` statement represents the imperative-reactive nature of SSRP, recovering sequential execution lost with the observer pattern. Parallel compositions allow for multiple `await` statements to coexist, which is necessary to handle concurrent events, common in reactive applications. Orthogonal abortion is the ability to abort an activity from outside it, without affecting the overall consistency of the program (e.g., properly releasing global resources).

In this work, we extend the Esterel-based language CÊu with a new abstraction mechanism, the organisms, that encapsulate parallel compositions with an object-like interface. In brief, organisms are to SSRP like procedures are to SP, i.e., one can abstract a portion of code with a name and manipulate (call) that name from multiple places. Unlike procedure calls in multi-threaded applications, organisms have deterministic behavior and do not require explicit synchronization. Unlike Simula objects, organisms react independently to the environment and do not depend on cooperation, i.e., once instantiated they become alive and reactive (hence the name organisms). Furthermore, organisms are subject to lexical scope and automatic memory management for both static and dynamic instances, not relying on heap allocation at all.

The rest of the paper is organized as follows: Section 2 presents SSRP through CÊu with its underlying synchronous concurrency model and parallel compositions. Section 3 describes the organisms abstraction with static and dynamic instantiation, lexical scope, and automatic memory management. Section 4 discusses related work. Section 5 concludes the paper.

## 2. SSRP WITH CÊU

CÊu is a concurrent language in which the lines of execution, known as trails, react all together continuously and in synchronous steps to external stimuli. The introductory example in Figure 1 defines an input event `RESET` (line 1), a shared variable `v` (line 2), and starts two trails with the `par` construct (lines 3-14): the first (lines 4-8) increments variable `v` on every second and prints its value on screen; the second (lines 10-13) resets `v` on every external request to `RESET`. Programs in CÊu can access C libraries of the underlying platform directly by prefixing symbols with an underscore (e.g., `printf(<...>)`, in line 7).

### 2.1 Synchronous concurrency

In CÊu, a program reacts to an occurring event completely before handling the next. A reaction represents a logical instant in which all trails awaiting the occurring event awake and execute, one after the other, until they await again or terminate. During a reaction, the environment is invariant and does not interrupt the running trails. If multiple trails

![Figure 1: Introductory example in CÊu.](image-url)

react to the same event, the scheduler employs lexical order to preserve determinism, i.e., the trail that appears first in the source code executes first. To avoid infinite execution for reactions, CÊu ensures that all loops contain `await` statements.

As a consequence of synchronous execution, all consecutive operations to shared variable `v` in Figure 1 are atomic (until reaching the next `await`) because reactions to events `is` and `RESET` can never interrupt each other. In contrast, in asynchronous models with nondeterministic scheduling, the occurrence of `RESET` could preempt the first trail during an increment to `v` (line 6) and reset it (line 12) before printing it (line 7), characterizing a race condition on the variable. The example illustrates the (arguably simpler) reasoning about concurrency under the synchronous execution model.

The synchronous model also empowers SP with an orthogonal abortion construct that simplifies the composition of activities. The code that follows shows the `par/or` construct of CÊu which composes trails and rejoins when either of them terminates, properly aborting the other:

```
par/or do
  <trail-1>
with
  <trail-2>
end <subsequent-code>
```

The `par/or` is regarded as orthogonal because the composed trails do not know when and how they are aborted (i.e., abortion is external to them). This is possible in synchronous languages due to the accurate control of concurrent activities, i.e., in between every reaction, the whole system is idle and consistent. CÊu extends orthogonal abortion to also work with activities that use stateful resources from the environment (such as file and network handlers), as we discuss in Section 2.2.

Abortion in asynchronous languages is challenging because the activity to be aborted might be on a inconsistent state (e.g., holding pending messages or locks). This way, the possible (unsatisfactory) semantics for a hypothetical `par/or` are: either wait for the activity to be consistent before rejoining, making the program unresponsive to incoming events for an arbitrary time; or rejoin immediately and let the activity complete in the background, which

---

3In this work, the term parallel composition does not imply many-core parallel execution.

4The actual implementation enqueues incoming input events to process them in further reactions.

5We use the term activity to generically refer to a language’s unit of execution (e.g., thread, actor, trail, etc.).
may cause race conditions with the subsequent code. In fact, asynchronous languages do not provide effective abortion: Java’s Thread.stop primitive has been deprecated [19]; pthread’s pthread_cancel does not guarantee immediate cancellation [2]; Erlang’s exit either enqueues a terminating message (which may take time), or unconditionally terminates the process (regardless of its state) [1]; and CSP only supports a composition operator that “terminates when all of the combined processes terminate” [16]. As an alternative, asynchronous activities typically agree on a common protocol to abort each other (e.g., through shared state variables or message passing), which increases coupling among them with implementation details that are not directly related to the problem specification.

2.2 Parallel compositions
In terms of control structures, SSRP basically extends SP with parallel compositions, allowing applications to handle multiple events concurrently. Céu provides three parallel constructs that vary on how they rejoin: a par/and rejoins when all trails in parallel terminate; a par/or rejoins when any trail in parallel terminates; a par never rejoins (even if all trails in parallel terminate). The code chunks that follow compare the par/and and par/or compositions side by side:

```plaintext
input void START, STOP, RETRANSMIT;
loop do
  await START;
  par/or do
    await STOP;
    with loop do
      par/or do
        await RETRANSMIT;
        with par/and do
          await 1ms;
          <send-beacon-packet>
        end
      end
    end
  end
loop do
  par/and do
    <...> // the rest of the protocol
  end
end
```

Figure 2: Parallel compositions can describe complex state machines.

Consider the code in the left of Figure 3, which expands the sending trail of Figure 2 (line 14). The buffer packet is a local variable whose address is passed to function _send_enqueue. The call enqueues the pointer in the radio driver, which holds it up to the emission of SENDACK acknowledging the packet transmission. In the meantime, the sending trail might be aborted by STOP or RETRANSMIT requests (lines 5 and 9 in Figure 2), making the packet buffer go out of scope, and leaving behind a dangling pointer in the radio driver. Céu refuses to compile programs like this and requires finalization clauses to accompany stateful C calls [23]. The code in the right of Figure 3 properly dequeues the packet when the block of buffer goes out of scope, i.e., the finalization clause (after the with) executes automatically on external abortion.

```plaintext
var _pkt_t buffer;
<fill-buffer-info>
_send_enqueue(&buffer);
finalize
await SENDACK;
with _send_dequeue(&buffer);
end
await SENDACK;
```

Figure 3: Finalization clauses safely release stateful resources.

The example in Figure 2 relies on hierarchical par/or and par/and compositions to describe the state machine of a data collection protocol for sensor networks [14, 23]. The input events START, STOP, and RETRANSMIT (line 1) represent the external interface of the protocol with a client application. The protocol enters the top-level loop and awaits the starting event (line 3). Once the client application makes a start request, the protocol starts three other trails: one monitors the stopping event (line 5); one periodically transmits a status packet (lines 7-17); and one handles the remaining functionality of the protocol (collapsed in line 19). The periodic transmission is another loop that starts two other trails (lines 9-16): one to handle an immediate retransmission request (line 9); and one that actually transmits the status packet (lines 11-15). The transmission (collapsed in line 14) is enclosed with a par/and that takes at least one minute before looping, to avoid flooding the network with packets. At any time, the client may request a retransmission (line 9), which terminates the par/or (line 8), aborts the ongoing transmission (line 14, if not idle), and restarts the loop (line 7). The client may also request to stop the whole protocol at any time (line 5), which terminates the outermost par/or (line 4) and aborts the transmission and all composed trails. In this case, the top-level loop restarts (line 2) and waits for the next request to start the protocol (line 3), ignoring all other requests (as the protocol specifies). The example shows how parallel compositions can describe complex state machines in a structured way, eliminating the use of global state variables for this purpose [23].

2.3 Finalization
The Céu compiler tracks the interaction of par/or compositions with local variables and stateful C functions (e.g., device drivers) in order to preserve safe orthogonal abortion of trails.
3. ORGANISMS: SSRP ABSTRACTIONS

In SP, the typical abstraction mechanism is a procedure, which abstracts a routine with a meaningful name that can be invoked multiple times with different parameters. However, procedures were not devised for continuous input, and cannot retain control across reactions to the environment.

Céu abstracts data and control into the single concept of organisms. A class of organisms describes an interface and an execution body. The interface exposes public variables, methods, and also internal events (exemplified later). The body can contain any valid code in Céu, including parallel compositions. When an organism is instantiated, its body starts to execute in parallel with the program. Organism instantiation can be either static or dynamic.

The example in Figure 4 introduces static organisms with three code chunks: CODE-1 blinks two LEDs with different frequencies in parallel and terminates after 1 minute; CODE-2 abstracts the blinking LEDs in an organism class and uses two instances of it to reproduce the same behavior of CODE-1; CODE-3 is the semi-grammatically equivalent expansion of the organisms bodies, which resembles the original CODE-1.

In CODE-2, the Blink class (lines 1-9) exposes the pin and dt properties, corresponding to the LED I/O pin and the blinking period, respectively. The application then creates two instances, specifying those properties in the constructors (lines 12-15 and 17-20). Inside constructors, the identifier this refers to the organism under instantiation. The constructors automatically start the organisms bodies (lines 5-8) to run in parallel in the background, i.e., both instances are already running before the await lmin (line 22).

CODE-3 is semantically equivalent to CODE-2, but with the organism constructors and bodies expanded (lines 10-17 and 19-26). The generated par/or (lines 9-29) makes the instances concurrent with the rest of the application (in this example, the await lmin in line 28). Note the generated await FOREVER statements (lines 17 and 26) to avoid the organisms bodies to terminate the par/or. The _Blink type (lines 1-4) corresponds to a simple datatype without an execution body. The actual implementation of Céu does not expand the organisms bodies like in CODE-3; instead, a class generates a single code for its body, which is shared by all instances (just like objects share class methods).

The main distinction from organisms to standard objects is how organisms can react independently and directly to the environment. For instance, organisms need not be included in observer lists for events, or rely on the main program to feed their methods with input from the environment. Although the organisms run independently from the main program, they are still subject to the disciplined synchronous model, which keeps the whole system deterministic, as the equivalent expansion of CODE-3 suggests (and based on lexical scheduling described in Section 2.1).

The memory model for organisms is similar to stack-living local variables of procedures in SP, featuring lexical scope and automatic management. Note that CODE-2 uses a do-end block (lines 11-23) that limits the scope of the organisms for 1 minute (line 22). During that period, the organisms are accessible (through b1 and b2) and reactive to the environment (i.e., blinking continuously). After that period,
reactive systems have to deal with resource virtualization that requires dynamic allocation, such as multiplexing protocols in a network, or simulating entire civilizations in a game. Dynamic allocation for organisms extends the power of SSRP to handle virtual resources in reactive applications.

Céu supports dynamic instantiation of organisms through the spawn primitive. The example that follows spawns a new instance of Unit (previously defined in Figure 5) on every second and moves it to a random position:

```plaintext
loop do
  await 1s;
  spawn Unit with
    this.pos = _rand() % 500;
    this.dst = _rand() % 500;
  end;
end
```

Dynamic instances also execute in parallel with the rest of the application, but have different lifetime and scoping rules than static ones: A static instance has an identifier and a well-defined scope that holds its memory resources; A dynamic instance is anonymous and outlives the scope that spawns it. In the example, the spawned units outlive the enclosing loop iterations. Due to the lack of an explicit identifier or reference, a dynamic instance can control its own lifetime: once its body terminates, a dynamic organism is automatically freed from memory. This does not apply for a static instance because its memory is statically preallocated and its identifier is still accessible even if its body terminates.

The code that follows redefines the body of the Unit class of Figure 5 to terminate after 1 hour, imposing a maximum life span in which a unit can react to move requests. After that, the body terminates and the organism is automatically freed (if dynamically spawned):

```plaintext
class Unit with
  <...> // interface
  do
    par/or do
      <...> // moving trail
      with
        await 1h;
      end
    end
  end
end
```

The lack of scopes for dynamic organisms prevents orthogonal abortion, given that there is no way to externally abort the execution of a dynamic instance. To address orthogonal abortion, Céu provides lexically scoped pools as containers that hold dynamic instances of organisms. The example that follows declares the units pool to hold a maximum of 10 instances (line 3):

```plaintext
input void CLICK;
  do
    pool Unit[10] units;
    par/or do
      loop do
        await 1s;
        spawn Unit in units with
          <...> // constructor
        end;
      end;
    end
  end
end
```

Figure 5: Organism manipulation through events.

The organisms go out of scope and, not only they become inaccessible, but their bodies are automatically aborted, as the expansion of CODE-2L makes clear: The par/or (lines 9-29) aborts the organisms bodies after 1 minute (line 28), just before they go out of scope (line 30). The par/or termination properly triggers all active finalization clauses inside the organism bodies (if any), as discussed in Section 2.3. Lexical scope extends the idea of orthogonal abortion to organisms, as they are automatically aborted when going out of scope. In this sense, organisms are more than a cosmetic convenience for programmers because they tie together data and associated execution into the same scope.

In addition to properties and methods, organisms also expose internal events which support await and emit operations. In the example in Figure 5, the class Unit (lines 1-16) defines the position and destination properties pos and dst (lines 2-3), and the event move to listen for requests to move the unit position (line 4). The main program (lines 18-24) creates two units, requesting the first to move immediately to dst=300, and the second to move after 1 second to position 500. On instantiation, the organism body enters a continuous loop (lines 6-15) to handle move requests (line 8) while performing the ongoing moving operation (lines 10-13) in parallel. The par/or (lines 7-14) restarts the loop for every move request which updates the dst position. The moving operation (collapsed in line 11) can be as complex as needed, for example, using another loop to apply physics over time. The await FOREVER (line 13) halts the trail after the move completes and avoid restarting the outer loop. An advantage of event handling over method calls is that they can be composed in the organism body to affect other ongoing operations. In the example, the await move (line 8) aborts and restarts the moving operation, just like the timeout pattern of Section 2.2.

3.1 Dynamic organisms

Static embedded systems typically manipulate hardware with a one-to-one correspondence in software, i.e., a static piece of software deals with a corresponding piece of hardware (e.g., a sensor or actuator). In contrast, more general
A new unit is spawned in the pool once a second (note the 

in units, in line 7). Once the application receives a CLICK 

(line 12), the par/or (line 4) terminates, making the units 

pool to go out of scope and abort/free all units alive.

Pools with bounded dimension (e.g., pool Unit[10] units;), 

have static pre-allocation, resulting in efficient and deter-

ministic organism instantiation. This opens the possibility 

for dynamic behavior also in constrained embedded systems. 

If a pool does not specify a dimension (e.g., pool Unit[] 

units;), the instances go to the heap but are still subject to 

the pool scope. If a spawn does not specify a pool (e.g., spawn 

Unit;), the instances go to a predefined dimension-less pool 

in the top of the current class (and are still subject to that 

pool scope).

Support for lexical scope for both static and dynamic or-

ganisms eliminate garbage collection, free primitives, and 

memory leaks altogether.

3.2 Pointers to organisms

As organisms react independently to the environment, it 

is often not necessary to manipulate pointers to them. 

Nonetheless, a spawn allocation returns a pointer to the new 

organism, which can be later dereferenced with the operator ‘:’ (analogous to ‘->’ of C/C++;):

```
var Unit* ptr = spawn Unit;
ptr:pos = 0;  // this access is safe
await 2h;
emit ptr:move => 100;  // this access is unsafe
```

Pointers can be dangerous because they may last longer than 

the organisms to which they refer. The code above first ac-

quires a pointer ptr to a Unit. Then, it dereferences the 

pointer in two occasions: in the same reaction, just after ac-

quiring the pointer; and in another reaction, after 2h, when 

the pointed organism may have already terminated and been 

freed, leading to unspecified behavior in the program.

As a protection against dangling pointers, Céu enforces all 

pointer accesses across reactions to use the watching con-

struct which supervises organism termination, as illustrated 

in the left of Figure 6. The whole watching construct aborts 

whenever the referred organism terminates, eliminating pos-

sible dangling pointers in the program. The code in the 

right shows the equivalent expansion of the watching con-

struct into a par/or that awaits the special event __killed 

(which all classes manage internally).

Céu also refuses to assign the address of an organism to a 

pointer of greater scope, as illustrated below:

```
var Unit* ptr;
do
    var Unit u;
    ptr = u;  // illegal attribution
end
ptr:pos = 0;  // unsafe access ("u" went out of scope)
```

A more typical use of pointers to organisms is inside a pool 

iterator which acquire temporary pointers to all of its alive 

instances. To preserve pointer accesses safe, iterators cannot 

await. The example that follows iterates over the units pool 

to check for collision among units:

```
loop (Unit*) u in units do
    emit u:move => _rand() % 500;
end
```

Figure 6: Watching an organism pointer (in the left) 

and the equivalent expansion (in the right).

```
pool Unit[10] units;
\(...\)
loop (Unit*) u in units do
    if <check-collision=u1-vs-u2> then
        emit u1:move => _rand() % 500;
    end
    emit u2:move => _rand() % 500;
end
```

4. RELATED WORK

Simula is a simulation language that introduced the con-

cepts of objects and coroutines [12]. The syntactic structure 
of classes in Simula is very similar to Céu, exposing an inter-

face that encapsulates an execution body. However, the un-

derlying execution models are fundamentally distinct: Céu 
employs a reactive scheduler to resume trails based on exter-

nal stimuli, while Simula relies on cooperation (i.e., detach 
and resume calls, at the lowest level). Simula has no no-

tion of compositions, with each object having a single line 
of execution. In particular, the lack of a par/or precludes or-

thogonal abortion and many derived Céu features, such as 
lexically scoped organisms, finalization, and reference watch-

ing. Without scopes, Simula objects have to live on the heap 
and rely on garbage collection.

Some previous work extend Esterel to provide dynamic syn-

chronous abstractions [9, 8, 10]. In particular, Reactive-

ML [18] is a functional variant of Esterel with rich dy-

namic synchronous abstractions through processes. How-

ever, these languages rely on heap allocation and/or garbage 
collection and may not be suitable for constrained embedded 
systems. They also lack a finalization mechanism that hin-

ders proper orthogonal abortion in the presence of stateful 
resources.

Finally, the main distinction to existing work is how Céu 
incorporates to SSRP the fundamental concept in SP of lex-

ically scoped variables. All constructs of Céu have a clear 
and unambiguous lifespan that can be inferred statically from 
the source code. Lexical scope permeates all aspects of the 
language: Any piece of data or control structure has a 
well-defined scope that can be abstracted as an organism 
and safely aborted through finalization. Even dynamic in-

stances of organisms reside in scoped pools with the same 
properties.

Functional Reactive Programming [26] contrasts with SSRP 
as a complementary programming style for reactive appli-

cations. We believe that FRP is more suitable for data-

intensive applications, while SSRP, for control-intensive ap-
lications. On the one hand, FRP uses declarative formulas 
to specify continuous functions over time, such as for physics
or data constraints among entities, while SSRP requires explicit loops to update data dependencies continuously. On the other hand, describing a sequence of steps in FRP requires to encode explicit state machines so that functions can switch behavior depending on the current state.

In the asynchronous spectrum of concurrency, a number of actor-based languages extend objects with independent execution contexts that communicate exclusively through message passing [25, 6, 24, 21]. On the one hand, the inherent nondeterministic execution of actors demands full state isolation which makes distribution and many-core parallelism more straightforward. On the other hand, the implicit synchronization in CÉu provides safe data sharing and global consensus about the overall state of the system, enabling abortion and lexical scopes for compositions.

5. CONCLUSION
CÉu provides comprehensive support for structured synchronous reactive programming, extending classical structure programming with continuous interaction with the environment.

CÉu introduces organisms which reconcile data and control state in a single abstraction. In contrast with objects, organisms have an execution body that can react independently to stimuli from the environment. An organism body supports multiple lines of execution that can await events without losing control context, offering an effective alternative to the infamous “callback hell”. Both static and dynamic instances of organisms are subject to lexical scope with automatic memory management, which eliminates memory leaks and the need for a garbage collector.

CÉu is suitable for wide range of reactive applications and platforms. We have been experimenting with it in constrained platforms for sensor networks as well as in full-fledged computers and tablets for games and graphical applications. We have also been teaching CÉu as an alternative language for sensor networks for the past two years in high-school and undergraduate levels. Our experience shows that students take advantage of the sequential style of CÉu and can implement non-trivial reactive programs in a couple of weeks.
